11
12 **Abstract**

13 In the context of increased coastal hazards due to variability in storminess patterns, the
14 danger of coastal damages and/or morphological changes is related to the sum of sea
15 level conditions, storm surge, maximum wave height and run up values. In order to better
16 understand the physical processes that cause the variability of the above parameters a 44
17 years reanalysis record (HIPOCAS) was used. The HIPOCAS time-series was validated
18 with real wave and sea-level data using linear and vector correlation methods. In the
19 present work changes in the magnitude, duration, frequency and approach direction of the
20 Atlantic storms over the Spanish Gulf of Cadiz (SW Iberian Peninsula) were identified by
21 computing various storm characteristics such as maximum wave height, total energy per
22 storm wave direction and storm duration. The obtained time-series were compared with
23 large-scale atmospheric indices such as the North Atlantic Oscillation (NAO) and the
24 East Atlantic pattern (EA). The results show a good correlation between negative NAO
25 values and increased storminess over the entire Gulf of Cadiz. Furthermore, negative
26 NAO values were correlated with high residual sea level values. Finally, a joint
27 probability analysis of storm and sea level analysis resulted in increased probabilities of
28 the two events happening at the same time indicating higher vulnerability of the coast and
29 increased coastal risks. The above results were compared with coastal inundation events
30 that took place over the last winter seasons in the province of Cadiz.

33 **1. Introduction**

34

35 Storm events are considered the main cause for shoreline change in many areas
36 worldwide (Fenster et al., 2001). Depending on the magnitude of the event and the
37 morphological characteristics of the coastline the change can be transient or persistent
38 (Anderson et al., 2010). Hence, storms are attributed an essential role in coastal long-term
39 evolution (decadal and centennial) despite the usually short time scale of their action
40 (Morton et al., 1995). Nowadays there is a growing socioeconomic need towards
41 innovative coastal management and evaluation of the risks associated with the
42 development in coastal plains (Van Dongeren et al., 2014). The combined effect of storm
43 activity and surge level changes can pose a risk on the coastal environment by eroding
44 the upper beach and inundating any low lying backshore area. In coastlines exposed to
45 long fetches, such as the Spanish Atlantic coast, large scale atmospheric phenomena are
46 the main source of storminess variability. Hence, the seasonal and inter-annual variability
47 or long term trends of the above processes can affect the risk distribution over a particular
48 stretch of coastline.

49

50 Specific trends in wave heights have long been observed in the North Atlantic (Bacon
51 and Carter, 1991; Carter and Draper, 1988; Dupuis et al., 2006; Feng et al., 2014b) and in
52 the Northeast Pacific (Allan and Komar, 2000). Furthermore, Bacon and Carter (1991)
53 observed a correlation between North Atlantic meridional atmospheric pressure gradient
54 and wave height. Woolf et al. (2002) established a relationship between wave height
55 anomalies and large scale atmospheric pressure patterns over the Northeast Atlantic on
56 the basis of satellite altimetry. Finally, Dodet et al. (2010) presented a larger influence of
57 the NAO over the south area of Europe using a 60 year long wave model forced by the 6h
58 wind field from National Centres of Environmental Prediction (NCEP) reanalysis project
59 (Kalnay et al., 1996).

60

61 Traditionally the NAO and other climatic indices have been mainly linked with
62 temperature, precipitation and large scale circulation patterns. Recent studies have also

63 focused on analysing the response of sea level variability to NAO, but always at a broad
64 spatial scale (Efthymiadis et al., 2002; Tsimplis and Shaw, 2008; Tsimplis et al., 2006;
65 Woolf et al., 2003). Main findings are that the NAO influence on sea level is dominant in
66 winter and represents one of the causes of the high inter-annual variability of sea level
67 during this season. Moreover, Woolf et al. (2003) suggest that NAO effects are probably
68 similar in the open ocean and along coastlines in large geographical areas, although they
69 might sometimes be masked by local phenomena.

70

71 Regional correlations between mean monthly wave height and NAO values have been
72 performed by various researchers (Bertin et al., 2013; Dodet et al., 2010; Feng et al.,
73 2014a; Rangel-Buitrago and Anfuso, 2013; Woolf et al., 2003). The impact of storms on
74 shoreline variability has been widely demonstrated (e.g. (Cooper et al., 2004; List et al.,
75 2006; Morris et al., 2001). However, a direct relationship between inter-annual wave
76 variability and coastal response has not been linked to NAO because of the general lack
77 of long-term and detailed coastal topographic data and the influence of other local and
78 regional aspects on coastal changes, such as geological framework (Jackson et al., 2005).
79 Recently O'Connor et al. (2011) demonstrated a tentative link between coastline
80 topography and NAO-modulated external forcing, by focusing in small and well
81 constrained tidal inlets of northwest of Ireland. Thomas et al. (2011) derived a negative
82 correlation between beach rotation and volume with the NAO for the southwest Welsh
83 coast. In the same way, using the SOI climatic index and the data-set of Narrabeen Beach
84 in Australia a relation between beach rotation was linked to the variability of wave
85 characteristics (Harley et al., 2009; Ranasinghe et al., 2004; Short et al., 2000).

86

87 Although it is well known that NAO affects the latitudinal aspects of storm tracks
88 variability over the Atlantic (Keim et al., 2004; Rogers, 1997) an in-depth investigation
89 of the joint influence on the wave storminess and sea surface height variability and the
90 associated coastal hazards in the Gulf of Cadiz has not yet been undertaken. The present
91 work focuses in the coastal area of the northern part of the Gulf of Cadiz and goes
92 beyond the separate analysis of wave and residual sea level as it investigates the
93 combined occurrence of the phenomena and their contribution to the increasing severity

94 of coastal hazards. Furthermore, other aspects of wave storminess are examined such as
95 the storm significant wave height, the storm direction and the total amount of storm hours
96 in a month. A description of the study area, wave and sea level data sets is presented,
97 followed by a section focused on the validation exercise and correction fittings that were
98 employed in order to improve the results of the hindcast models for storm conditions.
99 Then the inter-annual variability of the record is presented and correlations with large
100 scale climatic indices are undertaken. Finally, discussion and conclusions of the results
101 obtained and comparison with other work are detailed.

102

103 **2. Study area**

104 The Gulf of Cadiz is the sub-basin that connects the Atlantic Ocean with the
105 Mediterranean Sea through the Strait of Gibraltar. Its northern and southern boundaries
106 are, respectively, the southwest coast of the Iberian Peninsula and the Atlantic coast of
107 Morocco (Figure 1). As an Atlantic exposed coast it is influenced by large scale oceanic
108 weather systems that cross the North Atlantic following an eastward path, that determine
109 the patterns of precipitation, wind and long-fetch waves. The storms generated by these
110 systems are the principal cause of transient erosion in the area (Del Rio, 2007). On a local
111 scale, the orientation of the coastline and the local physiographic characteristics result in
112 sheltering effects to the north component winds and funnelling effects to south and east
113 component winds due to the complex orography of the Strait of Gibraltar (Dorman et al.,
114 1995). The prevailing wind and wave fields are from WSW directions (Figure 1), with a
115 yearly average significant wave height of 1 m comprised of both sea and swell,
116 generating a predominant longshore current towards the E and SE (Benavente et al.,
117 2000). Waves with north component are not frequent within the Gulf of Cadiz due to the
118 sheltering effect of the Cape St. Vincent (Figure 1) where significant diffraction and
119 attenuation takes place. In general the northern Gulf of Cadiz is characterized by a lower
120 energy wave climate than the western coastlines of the Iberian Peninsula (Loureiro et al.,
121 2013). Storm events are generally frequent over the autumn and winter months with
122 significant wave height values reaching up to 7m. The less frequent wave storm events in
123 the Gulf of Cadiz have easterly directions (wave rose in Figure 1) but they do not produce
124 high waves to the north-eastern part of the Gulf due to their limited fetch. Due to the

125 coastline orientation, these limited fetch storm waves affect only the north-western part
126 of the Gulf of Cadiz.

127

128 In terms of tides the area can be described as semidiurnal with mean tidal range of 2.20 m
129 decreasing towards the Strait of Gibraltar. Changes in shoreline orientation along the
130 Gulf coast greatly influence the approach angle of waves, which diminishes progressively
131 towards the Southeast, generating less significant littoral currents close to the Strait of
132 Gibraltar and weaker longshore drift (Medina, 1991). The surface circulation over the
133 continental shelf is mainly wind-driven but it is also affected by local forcing
134 mechanisms, such as the Guadalquivir River discharge, and is subject to seasonal and
135 inter-annual variations deeply related to the seasonal variability of the open sea
136 circulation (Criado-Aldeanueva et al., 2009). The latter is greatly affected by the large-
137 scale atmospheric patterns over the Atlantic Ocean, roughly represented by the NAO
138 index (Criado-Aldeanueva et al., 2009).

139

140 **3. Methodology**

141

142 **3.1 Data description**

143 In the present work the nearshore nodes of a hindcast dataset (HIPOCAS data
144 hereinafter), located over the north coast of the Gulf of Cadiz were used. The dataset
145 consists of a 44-year reanalysis of meteorological, wave variables and sea level spanning
146 between January 1958 and December 2001 (Sebastiao et al., 2008). For the wave
147 simulation over the Gulf of Cadiz a grid of 5' was linked to a larger WAM model
148 (WAMDI-Group, 1988) of the Atlantic Ocean through a series of nested models (Gomez
149 Lahoz and Carretero Albiach, 2005). The wave model was initially forced by the NCEP
150 reanalysis wind fields. The ocean circulation and sea level variations were simulated with
151 the HAMSOM model over a grid of 10'x 15' taking into account wind and pressure
152 forcing. The hydrodynamic model was forced with boundary conditions from the REMO
153 atmospheric model (Sebastiao et al., 2008) that was in turn forced with NCEP data. The
154 sea-level data represent the atmospherically-induced contribution and the associated
155 storm surges and do not have a tidal signal, or the contribution of the steric effect on sea-

156 level (Sebastiao et al., 2008). The output time-step was 3 hours for all the parameters.
157 From the above data set five stations were selected that cover the entire north coast of the
158 Gulf of Cadiz (Figure 1). From west to east the selected stations are: Faro, that represents
159 the most exposed part of the Gulf of Cadiz with a narrow shelf and a steep continental
160 slope; Huelva and Seville, located further to the east, at the widest part of the continental
161 shelf and partially sheltered from the west and north component winds by the Cape St.
162 Vincent; Cadiz station is located further to the southeast where the shelf width starts to
163 reduce and the coastline is more exposed to the Atlantic storms; finally the Zahara station
164 is largely dominated by the Gibraltar Strait conditions and is characterized by the absence
165 of continental shelf and reduced tidal range. In terms of wave data the coastal buoy of
166 Cadiz managed by Spanish Port Authorities and the buoy of Faro managed by the
167 Portuguese Hydrographical Office (Figure 1) were selected for validation purposes since
168 they provided directional wave measurement overlapping with the model data.

169

170 **3.2 HIPOCAS data validation**

171 An extensive validation exercise was undertaken by Mendez et al. (2006) between the
172 HIPOCAS wave data and wave buoy data collected around the Spanish coasts. However,
173 in order to optimize the results in the Gulf of Cadiz, a new correction was applied in the
174 present study that consisted in: (i) fitting the model wave height to observations focusing
175 mainly in the case of storm conditions; (ii) evaluating differences between model and
176 measured wave directions using a vector correlation approach (Kundu, 1976). The wave
177 height validation was evaluated by calculating the bias and the Brier Skill Score (BSS).
178 The latter parameter relates the variance of the difference between data and model with
179 the variance of the data. BSS=1 means perfect skill, BSS=0 means no skill (Roelvink et
180 al., 2009). The wave direction validation was evaluated based on the Kundu coefficient
181 and mean angle rotation (θ). Both wind waves and swell were analysed together since
182 they coexist during storm events and no spectral information was available.

183

184 In order to obtain a statistically independent wave height data set of storm conditions a
185 peak over threshold analysis (POT) was used for the period with simultaneous model and
186 observation data (Kamphuis, 2000). The above analysis allowed producing a correction

187 based on the peak values of each storm and was then applied to the entire data set. The
188 threshold value for the POT analysis was set as 1.5m wave height (a threshold value
189 proposed by the local authorities for civil protection), and a storm independence criteria
190 (time between two consecutive independent storms) was calculated based on the integral
191 time scales of the autocorrelation function (Emery and Thomson, 2001). Higher storm
192 threshold values proposed for the area of Cadiz (Almeida et al., 2012; Del Rio et al.,
193 2012; Ribera et al., 2011) were also used but the fitting coefficients obtained were not
194 significantly different.

195

196 The corrected values of significant wave height (H_{sc}) improved the time series extracted
197 from the reanalysis data for storms with H_s higher than 3m, where the HIPOCAS data
198 had significantly and systematically overestimated the wave height approximately by
199 30%. A single model was constructed from both data series with a correlation coefficient
200 of $r=0.75$ and applied to all stations. Similar correlation coefficients were also obtained
201 for only the Faro data by Almeida et al. (2011). Separate analysis of Cadiz and Faro
202 buoys resulted in correlations that had statistically no significant differences. Typical
203 results are shown in Figure 2 for March 1995 for both stations, where it can be observed
204 that the corrected HIPOCAS data show better agreement during storm conditions with the
205 buoy data. For the data set relative bias values of 0.02 instead of 0.29 for the uncorrected
206 data and BSS of 0.60 instead of 0.43 were obtained for the buoy of Faro. For the case of
207 Cadiz buoy similar values were calculated with relative bias decreasing from -0.35 to -
208 0.02 and BSS increasing from 0.41 to 0.66.

209

210 The agreement between the original (uncorrected) model data and buoy data, in both Faro
211 and Cadiz wave buoys, was tested for wave height and direction simultaneously using the
212 Kundu (1976) vector correlation approach. This correlation method produces a
213 coefficient between the directional wave heights of the two time series and the main
214 angle (θ) through which the first series would have to be rotated anticlockwise to match
215 the direction of the second series. Although overlapping of directional wave data between
216 the buoy of Cadiz and the HIPOCAS data only exists over part of 2001, the period is long
217 enough to cover both calm and stormy conditions. For the case of Faro the overlapping

218 period was much longer (1997-2001). The correction coefficients calculated for the two
219 time series were not statistically different; hence a common correction equation was
220 derived for both sites and then applied to all the wave data.

221

222 Differences in wave propagation direction between the measured and modelled data are
223 presented against the significant wave height in Figure 3. There is a large scatter in
224 directions for wave heights lower than 1m in both sites. However, as it can be seen from
225 the point's density, large differences are only present over few events, while the majority
226 of the data show small deviations. Such deviations are reduced to a variance of 45 deg for
227 waves between 1-1.5m, also with larger densities concentrated in small differences. Data
228 from Faro present slightly larger deviations for the lower wave heights. This is probably
229 related to the diffraction processes that waves undergo at the Cape St. Vincent, which are
230 probably not fully resolved by the model resolution. For the higher wave heights the
231 directional scatter is minimized and the HIPOCAS data present a good agreement with
232 the observed data.

233

234 Using the vector correlation approach, the correlation coefficient obtained for the Cadiz
235 buoy was 0.71 with an average angle difference of 4.7 deg. For Faro the correlation
236 obtained was 0.76 with an average angle difference of -5.2 deg. In Figure 4 the E-W
237 (zonal) and N-S (meridional) components of the waves are plotted for both sites. A good
238 agreement is observed between both components, particularly for large storm events of
239 southwest direction, which is the main oceanic storm approach direction. Similar results
240 were also observed by Ribera et al. (2011) for the same data set. The locally generated
241 small storms with predominant southeast directions are not well represented by the model
242 probably due to spatial constraints of the atmospheric forcing that cannot resolve the
243 local east wind acceleration over the Strait of Gibraltar (Figure 4, around 11/08/2001) and
244 the short fetch of those waves. These locally generated storms are not affecting the
245 eastern coastline of the Gulf of Cadiz, because of the short fetch and its general
246 orientation. However, the above events can generate coastal erosion events further west,
247 over the coast of southern Portugal (Garcia et al., 2005).

248

249 No validation to the sea level data was applied here because the calibrated time series
250 (Sebastiao et al., 2008) are the only available in the area for the reanalysis period. The sea
251 level reanalysis carried out for the HIPOCAS data along the coasts of the Iberian
252 Peninsula presented good results (Sebastiao et al., 2008). For example, in the area of the
253 Gulf of Cadiz (tidal station Seville) the results were under-predicting the observations
254 with a RMSE of 12.61 only for the extreme peak of the storms. This discrepancy could be
255 due to the tidal gauge location (close to estuary mouth) where the measured water levels
256 are locally affected by the river discharge; however, this do not influence the general
257 surge level on the continental shelf (Laiz et al., 2013).

258

259 **3.3 Data analysis**

260 The corrected time series were used to calculate the monthly, seasonal and annual values
261 of the wave heights and directions and sea level in order to identify the wave climatology
262 in the area. Furthermore, storminess indices were calculated on a monthly basis in order
263 to be compared with climatic indices. The wave storminess indices obtained were: the
264 number of individual storms per month (storm number, SN); the storm significant wave
265 height H_{st} which corresponds to the monthly average ($\overline{H_s}$) of wave heights (H_s) for the
266 values above the threshold (H_{th})

$$H_{st} = \overline{H_s} | H_s > H_{th}$$

267

268 Finally, the number of hours when the storm threshold was exceeded divided by the total
269 number of hours per month (Storm Duration Ratio, SDR) was also calculated

270

$$SDR = \frac{\sum_{i=1}^N t_i | H_i > H_{th}}{\sum_{i=1}^N t_i}$$

271

272 where N is the number of model output per month and H_{th} is the storm threshold. For both
273 indices the wave height threshold and storm independence criteria remained the same as
274 in the POT analysis. SDR is a value similar to the percentage of run length introduced by
275 Feng et al. (2014a). Additionally the total storm energy per month was calculated as the
276 sum of wave energy above the storm threshold.

277

278 The computed indices were correlated with the climatic indices that influence weather
279 patterns over Europe, namely the North Atlantic Oscillation (NAO), the East Atlantic
280 Pattern (EA), the Scandinavia Pattern (SCAN) and the Polar/ Eurasia Pattern (POL). The
281 monthly data corresponding to the HIPOCAS dataset were obtained from NOAA climate
282 centre and were calculated from the rotated EOF of the 500 hPa geopotential height. The
283 SCA and POL did not present any significant correlation; hence the results are not
284 presented. Significant differences between two correlation coefficients were tested using
285 the Fisher r-to-z transformation (Fisher, 1970). This method converts first each
286 correlation coefficient into a z -score. Then, making use of the sample size employed to
287 obtain each coefficient; these z -scores are compared.

288

289 Furthermore, a detailed study of surge levels given a specific wave height ($f_{S|Hs}$) was
290 studied at a storm event timescale. For the joint probability estimation of the residual sea
291 level (SLres) and Hsc were jointly used in POT analysis. For each storm event identified
292 by the POT analysis the peak Hsc and peak SLres were selected in order to construct a
293 contingency table. Tidal variations were not taken into account since in the Iberian
294 Peninsula tidal–surge energy transfer is low (Ratsimandresy et al., 2008). Combined
295 wave and SLres probability function ($f_{SLres,Hs}$) events was undertaken parting from the
296 assumption that the surge elevation probability function (f_s) is not independent of the
297 significant wave height probability function (f_{Hs}) for waves above the threshold.

298

$$f_{Hs,RSL}(Hs, RSL) = f_{RSL|Hs}(RSL|Hs) \cdot f_{Hs}(Hs)$$

299 For the calculation of join probability the initial POT analysis results were used in order
300 to construct a contingency table with storm events and the associated SLres.

301

302 **4. Results and Discussion**

303

304

305

306 **4.1 Wave and Residual Sea Level Climate**

307 The mean annual cycle for the corrected significant wave height (H_{sc}) and the associated
308 wave directions for the coastal area of the northern Gulf of Cadiz are presented in Figure
309 5a and 5b. The average wave heights over the area are higher during the winter months
310 and part of the autumn. From the comparison of corrected significant wave heights (H_{sc})
311 and their associated directions it can be seen that there is a high energy period starting in
312 November and extending up to March, when the mean wave heights are higher ($H_{sc} \approx$
313 1m) and from more southerly directions. The same pattern is present for all stations with
314 some differences in Huelva and Seville where the mean significant wave height is lower
315 and mean direction of propagation has a stronger southern component, due to the shelter
316 effect of the Cape St Vincent. These values classify the coastline as a mixed energy,
317 wave-dominated coast according to (Davis and Hayes, 1984). Over the rest of the year
318 mean wave height is significantly lower with more westerly directions. This annual
319 variability represents the typical wave climatology of the region. Based on the above
320 results the wave climate in the Gulf of Cadiz can be separated in a storm (November -
321 March) and a calm (April - October) season. These results are in agreement with previous
322 wave climate studies (Dodet et al., 2010; Lozano et al., 2004) on the area and with the
323 seasonal morphological behaviour of the beach (Benavente et al., 2002). In terms of peak
324 period (T_p , Figure 5c) the seasonal pattern is repeated with higher values of T_p during the
325 storm season and lower ones during the calm season. All stations present the same mean
326 monthly values with the only difference of Huelva (the most protected station) where T_p
327 values are smaller.

328

329 On the other hand the monthly residual sea level (SLres) variation (Figure 5d) presents an
330 inverse image, with higher SLres during the calm period and lower values during the
331 storm period. These results are in agreement with previous analysis of SLres records in
332 the area that show a seasonal cycle with a minimum in February and a maximum in
333 October, consistent with atmospheric pressure forcing in this region (Laiz et al., 2013).
334 The SLres annual signal ranges between about 4–6/5–6 cm from tide gauges/altimeter
335 measurements, respectively, the latter always showing slightly larger amplitudes
336 (Gomez-Enri et al., 2012; Laiz et al., 2013; Marcos et al., 2011; Marcos and Tsimplis,
337 2007).

338

339 **4.2 Correlations with climate indices**

340 The inter-annual variability of the storm significant wave height and storminess indices
341 did not show significant correlation with climatic indices. These results have been
342 reported before for the Faro station and NAO (Almeida et al., 2011) and seem to extend
343 over the entire Gulf of Cadiz. Other studies have concluded that the inter-annual
344 variability of Hs is partially controlled by NAO (Dodet et al., 2010; Woolf et al., 2002)
345 but Bertin et al. (2013) show that this relationship has a large spatial variability that
346 results in non-significant correlations over the Gulf of Cadiz. Also the same studies
347 concluded that no linear trend is present for Hs over the study area. This paper is focusing
348 on the monthly variability both for the storm and calm period as well as their
349 climatological anomalies.

350

351 Both the storm mean monthly values (mean value of significant wave height that exceeds
352 the storm threshold, 1.5 m) and their anomalies for the whole year and for the storm
353 seasons were tested against all indices that are linked with climate variability over
354 Europe, in order to investigate possible correlations with the wave parameters and SLres
355 in the Gulf of Cadiz. Significant correlations were obtained for the NAO and EA pattern.
356 Data showed correlation between the annual Hsc and NAO for all sites with values
357 between -0.27 for Faro and -0.34 for Seville, increasing for the storm season months to
358 values of around -0.58 (Table 1, Figure 6). However, the correlations between the mean
359 monthly anomalies and NAO show significant increase ($p < 0.01$) for the full year where
360 the correlation coefficient almost doubles, suggesting that NAO has an effect on the wave
361 variability that prevails during calm season as well. This variability could be due to
362 waves formed by local wind or to swell field being determined by the NAO over the
363 North Atlantic. This can have implications on the medium term shoreline evolutions
364 since the wave period characteristics during the calm season are responsible for the beach
365 accretion and recovery after the storms. For the storm season the anomaly correlations are
366 also higher but differences are small and not statistically significant. In terms of spatial
367 distributions there are no significant differences observed for the various locations
368 between NAO and the annual Hs for all cases. The physical explanation of the above

369 correlations could be attributed to the higher abundance of low pressure systems and the
370 increase in wind speed linked with the NAO and attributed to the southern shift of the
371 Atlantic storm tracks (Dodet et al., 2010; Keim et al., 2004).

372

373 Significant correlations but with low correlation coefficient values were observed
374 between NAO and monthly wave directions for the full year; the best correlation was
375 observed in Huelva but the coefficient did not exceed -0.20. Over the storm season
376 correlations did not improve but the significance levels decreased due to the lower
377 number of observations (220 instead of 528) that influences the degrees of freedom of the
378 correlations. The spatial distribution again did not show any significant variation.

379

380 The residual water levels also presented strong correlations with NAO especially during
381 the storm season months, showing a high correlation value between mean storm residual
382 water levels and NAO (-0.66 on average, $p < 0.01$). These results are in agreement with
383 previous studies in the area using the same reanalysis data for southern Europe (Marcos
384 et al., 2009). The main mechanism that drives the residual sea level response to the NAO
385 is both hydrostatic and non-hydrostatic (Woolf et al., 2003). Considering this, the
386 correlation between mean storm residual water level and NAO is possibly related to the
387 fact that the HIPOCAS dataset includes both processes, as it was modelled using a
388 barotropic version of the HAMSOM model (Ratsimandresy et al., 2008). All correlations
389 have a negative sign because wave height and residual sea level increase with negative
390 NAO values (Table 1).

391

392 For the case of EA the above parameters explain a small but statistically significant part
393 of the variability (Table 2) among which the most pronounced is that of the significant
394 wave height during the storm months. In all cases the correlation coefficients were
395 smaller than with NAO, as expected, since the EA is the second prominent mode of low-
396 frequency variability over the North Atlantic (Barnston and Livezey, 1987). For this
397 index the correlations are positive for wave height and direction but negative for SLres.
398 Positive EA values are responsible for zonally extended storm tracks that affect the
399 southern coasts of Europe (Wettstein and Wallace, 2010). Significant differences between

400 stations were only present for wave height correlations, where the lowest value obtained
401 (Huelva) was significantly different from the rest of the stations.

402

403 Correlations between wave directions during storms were stronger in the case of EA than
404 with the NAO. Correlations were positive with mean values around 0.20 to 0.3 and were
405 constant both for mean values and anomalies (Table 2). Apart from these correlations,
406 EA index presented negative correlations (between -0.36 and -0.46) with the wave
407 direction standard deviation during the storm season (Figure 7). These correlations
408 suggest a focusing of the storm around west direction during the positive EA and a
409 greater dispersion during negative EA. This dispersion is represented in the Gulf of Cadiz
410 with increased southern direction because of the negative skewness inherited to the data
411 by the coastline orientation.

412

413 Because the NAO and the EA represent different modes of the atmospheric variability i.e.
414 the percentage of variability expressed by the two indices is uncorrelated, the above
415 results suggest that storminess during negative NAO and positive EA phases can be
416 further increased. However, on a seasonal scale the indices can be correlated; hence, part
417 of the explained variance can be common (Martinez-Asensio et al., 2014). The physical
418 mechanism during NAO-negative and EA-positive phases is that the orientation of the
419 boundary between the positive and negative pressure anomalies crosses the North
420 Atlantic from northwest (60N, 60W) to southeast (45N, 10W), which is likely to
421 influence the meridional circulation intensity (Nesterov, 2009) and direct the storm tracks
422 towards south Europe and into the Gulf of Cadiz. Furthermore, average wind during
423 winter NAO-negative and EA-positive phases reveals patterns of westerly wind
424 (Martinez-Asensio et al., 2014) that can induce a net mass flux in the Gulf of Cadiz and
425 at the same time generate increased Hs (Fukumori et al., 2007). Similar average wind
426 patterns are also generated during positive SCAN phases but with a more pronounced
427 northern component; however, any generated waves by this wind pattern are not affecting
428 the northern part of the Gulf of Cadiz due to the sheltering effect of the Cape St. Vincent.

429

430 Apart from the mean monthly values and anomalies, specific storm indices calculated
431 above were also correlated with the climatic indices. Similar correlations (-0.52 and -
432 0.43, $p < 0.01$) were obtained between the SDR, which is a measure of the total time of the
433 Atlantic oriented storm activity per month, and the NAO for the storm season (Figure 8).
434 Higher values are observed for the more exposed stations (Faro, Cadiz and Zahara).
435 Special cases for the Atlantic storms were selected by gradually restricting the direction
436 of the incoming storm to pure westerly directions (data not shown). For these cases the
437 correlation coefficients remain practically unchanged in all stations except Seville and
438 Huelva, where the number of events drops dramatically due to the sheltering effect. The
439 Storm number also presented similar patterns to the SDR both in terms of NAO
440 correlations and spatial variability (data not shown).

441

442 The monthly storm wave height (H_{st}) obtained from individual storms produced a weaker
443 correlation (-0.41, $p < 0.01$) with NAO over the storm season. Similar results were
444 obtained for the total energy of the storm waves for each month where the correlation
445 coefficient with NAO was -0.45 ($p < 0.01$). However the correlation between SDR and the
446 mean monthly H_s was of the order of -0.90 for the study area, with no significant
447 variations between the stations. The above results suggest that although negative NAO
448 values increase the storminess over the study area, they do not control the magnitude of
449 the wave height which is probably affected by synoptic atmospheric patterns. On the
450 other hand there is a correlation with the number and total storm duration arriving to the
451 Gulf of Cadiz. Similar results were presented for the Norwegian Sea where no statistical
452 correlation was obtained between NAO and waves with low probability of exceedance
453 (largest waves) (Feng et al., 2014b); however it has to be noted that NAO correlations
454 with the largest 1% of H_s can reach $r = 0.83$ over the Northwest of Scotland (Wang and
455 Swail, 2001; 2002) but these correlations present large spatial variation over the North
456 Atlantic.

457

458 **4.3 Joint Probability**

459 Despite the opposite seasonal pattern followed by the H_{sc} and the SL_{res} presented in
460 Figure 4, sea level values during storms were found to deviate substantially from the

461 average seasonal cycle especially during the storms. The joint probability between these
462 parameters is presented in Figure 9, with similar patterns observed at all stations. A large
463 proportion of the events identified by the POT (50%) correspond to relatively low energy
464 events (<2.5 m Hsc), for which the SLres showed a large spread that is mainly
465 concentrated in positive values between 0 and 15cm. For the rest of the events a clear
466 trend is obtained where higher wave heights are observed together with positive SLres,
467 with values up to 35 cm for the extreme wave height events of 4-6.5 m that have a return
468 period in the area of Cadiz between 3 and 4 years respectively (Del Rio et al., 2012).

469

470 The stations of Seville and Huelva that are situated at the shadow zone of the Cape St.
471 Vincent receive less storm activity both in terms of number and magnitude but follow the
472 same probability patterns as the rest of the area. Besides, this zone shows the highest
473 values of storm surge probably due to the larger width of the continental shelf. In contrast
474 the areas of Zahara and Faro that are characterised by a relatively narrower continental
475 shelf present much lower surges for the similar or higher wave heights. These results
476 show dependence between the SLres and the peak storm Hsc and have wide implications
477 on the coastal hazards and the associated risk of coastal erosion and inundations of the
478 coastal plain (Del Rio et al., 2012).

479

480 In accordance with the correlation presented above between the storm variables and
481 NAO, the joint probability analysis was undertaken separately for positive and negative
482 NAO events. In general the ratio between storm events occurred during a positive NAO
483 and events occurred during a negative NAO phase is close to 1 for all sites (Table 3). For
484 NAO phases with an index higher/lower than ± 1 and ± 1.5 it can be seen that the
485 negative NAO phases present almost twice the events than the positive ones for the
486 central part of the Gulf (Seville and Huelva). On the contrary the two sites located at the
487 extremities of the Gulf of Cadiz (Faro and Zahara) do not show this pattern. This is partly
488 due to the strong easterly winds that can also create short-fetch storms for these areas,
489 such events are more frequent during positive NAO (Dorman et al., 1995). These events
490 are present in the wave record of Zahara due to the proximity to the Strait of Gibraltar
491 and in Faro due to the orientation of the coastline and the considerable easterly fetch.

492 Differences are not present in extreme NAO phases ($-2 > \text{NAO} > +2$) probably due to the
493 small number of events (Table 3).

494

495 The joint probability analysis for positive and negative NAO events with index
496 higher/lower than ± 1.5 is presented in Figure 10, where it can be seen that during strong
497 positive and negative phases of NAO the joint probability of the wave–surge follows a
498 different pattern. Positive NAO events (Figure 10 left panels) are concentrated in weak
499 storm events ($H_{sc} < 2.5\text{m}$) with mainly small SLres. On the other hand, for the negative
500 NAO events (Figure 10 right panels) the same pattern that was observed in the full data
501 analysis is repeated with a positive trend between storm wave heights and SLres. The
502 above results corroborate with the NAO correlations of Table 1; where during storm
503 season H_{sc} and SLres show significant correlations with NAO.

504

505 The joint probability results emphasize the importance of the NAO on coastal hazards.
506 The H_s and storm surge height drive the morphological evolution and coastal hazard
507 estimation in the Gulf of Cadiz shores according to Del Rio et al. (2012). This way,
508 severe coastal erosion and flooding events have been recorded in the area during negative
509 NAO phases, with a great socioeconomic impact. This impact is related to both direct
510 damage to coastal infrastructure and undesirable morphological changes in the coastal
511 area, such as long-term reduction in beach width or damage to dune ridges (Del Rio et al.
512 2012). One of the most significant periods in this respect occurred in the 2009-2010
513 winter season, when a peak in negative NAO index over the last 190 years was recorded
514 (Osborn, 2011). In that period a number of energetic storm events caused widespread
515 beach and dune recession and coastal flooding along the Gulf of Cadiz (Benavente et al.,
516 2013; Del Rio et al., 2010; Rangel-Buitrago and Anfuso, 2013; Vousdoukas et al., 2012).
517 Maximum wave heights of up to 8.4m were observed and SLres up to 0.50m were
518 recorded at the tidal station of Cadiz. In terms of H_s the storm had a return period of
519 20years; however, taking into account the prolonged duration of the storm (more than 20
520 days of storm conditions) the total event as a group of storms should have a much greater
521 return period according to Ferreira (2006). The associated damage on coastal assets
522 generated important economic losses, which for instance in Cadiz city beaches were

523 around 157,000 €(Lopez-Doriga et al., 2010) For this reason, the fact that Hs and storm
524 surge height have a high joint probability especially during the negative NAO phases is
525 of great importance and can be very useful at the design stage of coastal protection
526 systems and civil protection plans.

527

528 **5. Conclusions**

529

530 Reanalysis of wave and sea level data for a period of 44 years (HIPOCAS data) were
531 used to investigate the connection between large scale atmospheric circulation patterns
532 (NAO, EA) and the wave climate and sea level in the Gulf of Cadiz. Significant
533 improvement of the storm wave record was obtained after applying correction functions
534 derived from the coastal wave buoys in the area of Cadiz and Faro. In general, the
535 HIPOCAS data correctly represented the directional storm climate in the Gulf of Cadiz
536 and mainly the one coming from the northwestern Atlantic. The locally accelerated
537 easterly winds in the area of the Strait of Gibraltar are not well represented due to the
538 relative large scale of the re-analysis data. However, these events are not affecting storm-
539 related hazards along the coastline of the study area except for the zone of Faro, as they
540 are mostly related to high atmospheric pressure situations; furthermore, shoreline
541 orientation and short fetch determine a negligible impact of easterly waves along the
542 northeastern coast of the Gulf of Cadiz.

543

544 In terms of wave activity two seasons can be distinguished: the storm and the calm
545 season. The former extends from November to March and shows higher mean monthly
546 significant wave height and distinguishable wave period and direction than the calm
547 season. Based on these results further analysis was undertaken following the above
548 seasonal pattern and not the atmospheric season convention. NAO presented negative
549 correlations with the monthly parameters of the storm season. When the mean wave
550 climatology was subtracted from the data this correlation was extended to the entire year
551 (anomalies) suggesting influence of the NAO to the calm wave conditions . Positive
552 correlations were obtained with the EA pattern that probably represents the zonal
553 extension of the storm tracks over the study area during positive EA phases. Better

554 correlations were identified for the total storm hours (Storm Index) and the residual mean
555 sea level but not with the maximum wave height. The above results suggest that although
556 negative NAO values increase the storminess over the study area they do not control the
557 magnitude of the wave height, which is probably affected by mesoscale atmospheric
558 patterns. The combined NAO and EA patterns explain a large part of the mean wave
559 variability, also positive EA patterns are correlated with more westerly directions of the
560 storm waves.

561

562 Joint probability analyses showed dependence between storm conditions and positive
563 residual mean sea level on the basis of 367 events. This dependence is more pronounced
564 over storm events with large wave heights. Study of storm events over distinct NAO
565 index values showed a dominance of storm events during negative NAO phases. At
566 extreme negative NAO phases the coexistence of large SLres and large storm events are
567 present. This is not the case in positive NAO phases, where small storm events are
568 present with disperse SLres response. In terms of coastal hazards and risk the coexistence
569 of storm events and high SLres can potentially increase the vulnerability of the coastal
570 areas to erosion and/or flooding episodes. The fact that these two parameters have a high
571 joint probability especially during the negative NAO phases is of great importance and
572 can be very useful at the design stage of coastal protection systems and civil protection
573 plans. Furthermore, such result provides valuable information for understanding and
574 reconstructing the long-term coastline evolution of the Gulf of Cadiz due to the long
575 record of NAO index.

576

577 *Acknowledgments*

578 The authors would like to acknowledge Puertos del Estado for providing the wave buoy
579 data for the coastal area of Cadiz, and CEDEX for providing the HIPOCAS data. This
580 work has been supported by the MICORE project (EU grant FP7-ENV-2007-1-202798,
581 the GERICO project (CGL2011-25438) and the RISCKIT project (Resilience-Increasing
582 Strategies for Coasts - toolKIT", EU grand number 603458, www.risckit.eu). IL was
583 financially supported by the Spanish Ministry of Science and Technology ("Juan de la
584 Cierva Programme", the project ALCOVA (CTM2012-37839) and by the research group

585 RNM-337 of the PAI. TAP, JB and LdR were also supported by the research group
586 RNM-328 of the PAI. The contribution of the two reviewers in the improvement of the
587 manuscript is greatly acknowledged.
